

Disrupting Precision Agriculture: Making VRF Simpler.

Introduction:

The history of Precision Agriculture goes back to 1990 when GPS became available for public use. Since then the major milestones include Yield Monitors, Autosteering, Controlled Traffic, Touch Screen Computers and Moisture Sensors. However the end game for Precision Agriculture is Variable Rate Fertilization applications for nutrients including Nitrogen, Sulphur, Potassium and Phosphorous. Yet so few farmers have adopted VRF technologies. The most likely reason for the low take up of PA and VRF technologies is that there have been few examples of success can be credited to their use. It could also be that farmers find it too complex to translate data taken from the PA tools to VRF prescriptions to use on spreaders and sprayers.

The next piece of the PA Puzzle, i.e., On Combine NIR Analysis, offers a simple solution to the generation of VRF prescriptions based on using protein and yield maps to identify zones where plant growth and development has been limited by the amount of nutrients applied to the plants in the form of fertilizers.

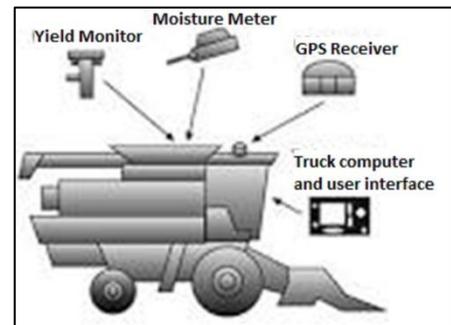

Fig. 1. Implementation of PA on combine harvesters since 1990.

Description:

On Combine NIR Analysis is a technology whereby protein, moisture and oil in grains and oil seeds are measured in real time as the combine harvests the grain from the field. Proteins are composed of Carbon, Hydrogen, Nitrogen, Sulphur and Oxygen. Specifically proteins contain approximately 17.5% Nitrogen and 3.5% Sulphur by weight. As such for every tonne of grain or oil seeds harvested from the field between 15 and 30kg of Nitrogen and 3 to 7kg of Sulphur are removed from the soil in the form of protein in the seeds.

Based on these relationships between protein and Nitrogen and Sulphur in the seeds, then the On Combine NIR Analyser provides a means of measuring Nitrogen and Sulphur availability and uptake across the field.

Moisture is the major factor that influences plant growth and development however Nitrogen is the most important nutrient that is required by plants in order to fully grow and produce seeds. Figure 2 shows the growth stages of cereal crops such as wheat and barley.

Nitrogen is required at all stages of the plant growth cycle and the majority of the Nitrogen is taken up during the Stem Elongation and Leaf Formation stages. However soil Nitrogen is critical at the Emergence stage because the plant needs Nitrogen for Tiller production. The number of Tillers should be between 6 and 8 in a healthy plant. If there is insufficient Nitrogen available in

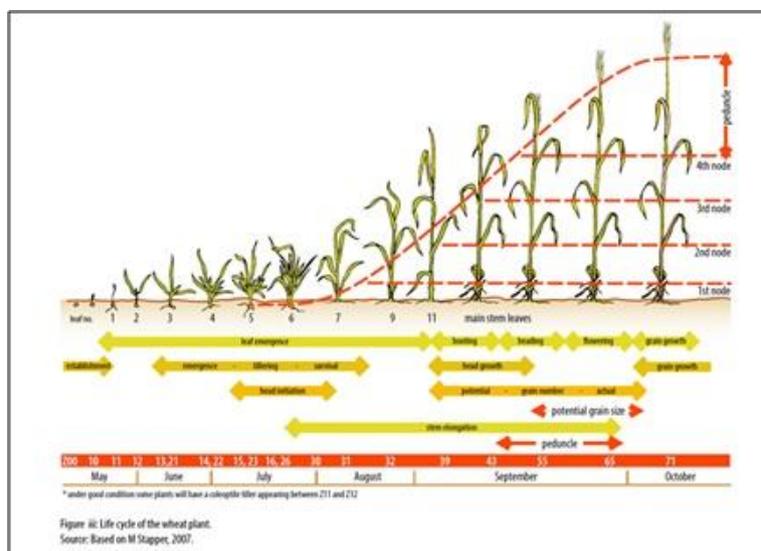

Fig. 2. Schematic of the stages of plant growth and development.

the soil at the Tillering stage, then the plant will produce less Tillers, i.e. 2 - 4. The number of Tillers dictates the number of stems and thereby heads of grains. Once the plant reaches the Stem elongation stage, then the plant cannot produce more Tillers or stems. The Yield Potential is set by the number of Tillers that growth to produce stems and heads.

As the stems grow and leaves emerge Nitrogen and Sulphur are required in the process of photosynthesis to produce sugars which the plant needs to drive cell production and thereby biomass. The Flowering stage is where the heads emerge and are pollinated. If there is insufficient Nitrogen available at this stage the plant may abort some heads in order to ensure that whatever Nitrogen is available will be used to see seeds grow and release. The last stage is the Filling of the seeds. If there is enough Nitrogen available then the seeds will fully develop with starch and protein. If there is excess Nitrogen then the plant will direct the Nitrogen towards producing protein. If there is enough water available throughout the growth and development stages then the Yield and the Protein will be determined by the availability and uptake of nutrients of which Nitrogen is the most important.

Protein/Nitrogen/Yield Balance:

Protein is related to Nitrogen as discussed above, however the relationship between Protein and Yield is not so obvious. In 2013, Greg McDonald and Peter Hooper, University of Adelaide, School of Agriculture, wrote an article for the GRDC titled: Nitrogen Decisions – Guidelines and rules of thumb. They referenced a paper written in 1963 by JS Russell for the Australian Journal of Experimental Agriculture and Animal Husbandry where he “described the idea of using grain protein concentration to assess the likelihood of N responsiveness in wheat cropping systems. He suggested

that yield responses were most likely when grain protein concentration was < 11.4%”. McDonald and Hooper went on to say, “Based on recent trial data, the general conclusion still appears valid: 100% of all trials where grain protein concentration of the unfertilised control was <8.5% were responsive to N and would have given yield response of 14kg/kg N. When grain protein concentration was >11.5%, only 32% of the trials were responsive to N and the mean yield response was zero”. They concluded; “While this relationship can’t be used to make in-season N decisions it may be useful in helping to assess the degree of N stress during the previous season and making post-harvest assessments of N management strategies, which can help in future plantings.” Other scientists and agronomists have written about the relationship between Protein content of the finished grain and the Yield. Steve Larocque, Beyond Agronomy, Alberta, Canada, publishes a newsletter that is read by more than 8000 precision farmers and agronomists around the world. Mr Larocque pointed out in his newsletter that there is a fine balance in applying Nitrogen to a barley crop where the objective is to optimize the yield and restrict the protein to less than 13%. He states, “The hard part is finding the right nitrogen rate to produce maximum yield with a protein that falls below 13% but higher than 12%. When your malt protein is lower than 12.5% you know you’re leaving yield on the table. If you shoot too high you end up with high protein and no malt selection.” Mr Larocque referred to the balance as the “Sweet Spot” where the yield was optimized and the protein grade realised the highest crop payments.

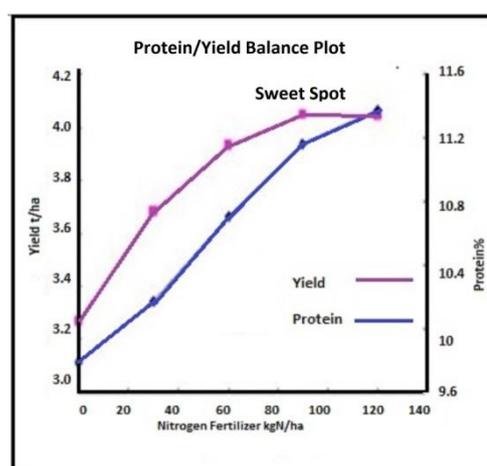

Figure 3. Grain yield (t/ha) and protein concentration (%) from 10 wheat varieties with 0, 30, 60, 90 and 120 kg/ha applied nitrogen in a trial at Parkes in 2011. (Brill et al, 2012, [Comparison-of-grain-yield-and-grain-protein-concentration-of-commercial-wheat-varieties](#)).

Thane Pringle, Independent Precision Agriculture, Yenda, NSW, explains how Nitrogen is used by plants and how Nitrogen is made available from the soil to the plants. He showed a plot (Figure 3.) of Yield vs. Nitrogen Fertilizer Application vs. Protein content of the grain. Brill et al state in their original paper, “As the rate of N supply is increased, yield will generally increase to a maximum level, whereas protein may continue to increase with further N application. This is demonstrated by the results from a trial at Parkes in 2011, sown as part of the GRDC- funded Variety Specific Agronomy Project (Figure 3). Wheat yield was responsive to N fertiliser but at a reducing rate where N was applied in 30 kg/ha increments. Yield was maximised with N application of 90 kg/ha. Protein increased linearly for each 30 kg/ha increment up to 120 kg/ha N. In this trial, yield appeared to be maximised at a grain protein concentration of 11.2 %, a useful ‘rule of thumb’ in deciding whether a crop was yield limited by N. “

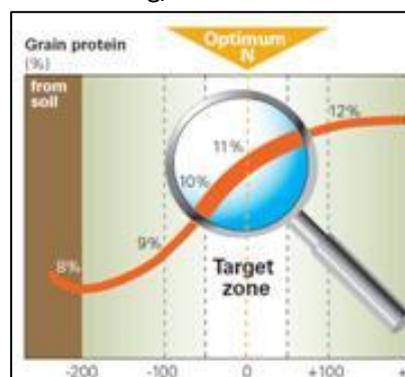

Figure 4. Nitrogen For Winter Wheats—Management Guidelines, Sylvester-Bradley, 2009

Professor Roger Sylvester-Bradley, UK, in a HGCV booklet titled Nitrogen for Winter Wheats—Management Guidelines, wrote, “Grain protein with optimum N for yield in feed varieties is consistently about 11% (1.9%N). Bread making varieties optimise for yield at around 12% protein and often need extra N to achieve a market specification of over 13%. Low grain protein – less than 10% for feed varieties – Indicates sub-optimal N use.

Protein/Yield Correlation:

Figure 5 shows four scenarios for the relationship between Protein and Yield.

- High Yield + High Protein
- Low Yield + High Protein
- Low Yield + Low Protein
- High Yield + Low Protein

The possible explanations for these scenarios are:
Low Yield + Low Protein = Insufficient Nitrogen

throughout all growth stages

Low Yield + High Protein = Insufficient Nitrogen in the

Tillering stage but sufficient Nitrogen in the Flowering and Filling stages

High Yield + Low Protein = Sufficient Nitrogen in the Tillering and Stem Elongation stages but insufficient Nitrogen in the Filling stages

High Yield + High Protein = Sufficient Nitrogen throughout all growth stages. This is the “Sweet Spot”.

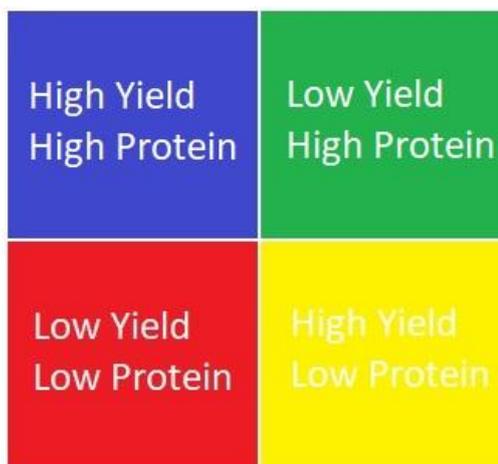

Figure 5. 4 Protein/Yield Correlation Scenarios

Based on these four scenarios, a field can be mapped by the correlation between Protein and Yield. Figure 6 shows the Protein and Yield maps for a wheat field from Broden Holland’s farm in Young NSW. Figure 7 shows the Protein/Yield Correlation map which plots the correlation between Protein and Yield within a 50m diameter. The plot has four colours, i.e. Blue: High Yield/High Protein, Red: Low Yield/Low Protein, Green: Low Yield/High Protein, Yellow: High Yield/Low Protein. The Blue areas in the Correlation map are the “Sweet Spots”, i.e. High Yield and High Protein. However the Red, Green and Yellow areas have performed poorly.

According to the experts referenced above, the Yellow areas would most likely have responded to additional Nitrogen fertilizer being added. Wherever the Protein levels in the finished grain were below 11.5%, then the crop did not reach its full Yield Potential. For the following crop, 2017, the farmer applied a simple Variable Rate Fertilization strategy as follows:

Protein < 11.5% = 120kg/ha
 Protein 11.5 – 12.5% = 80kg/ha
 Protein > 12.5% = 60kg/ha

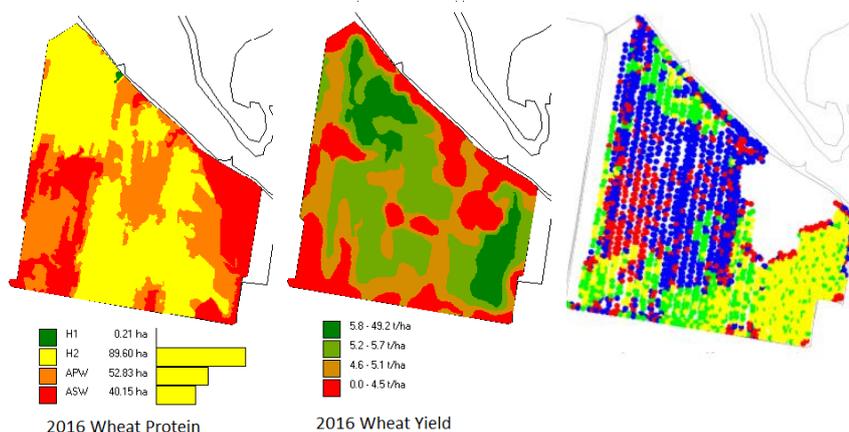

Figure 6. Protein and Yield Maps, 2016.

Figure 7. Protein/Yield Correlation Maps

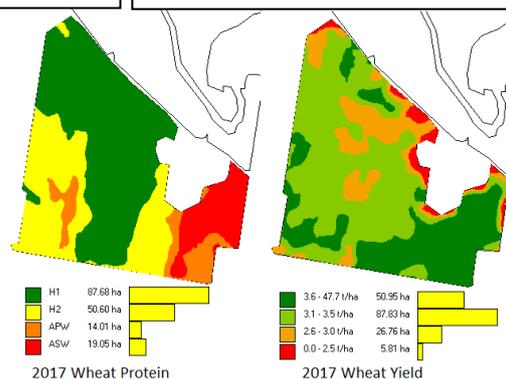

Figure 8. Protein and Yield Maps, 2017

Figure 8 shows the Protein and Yield maps for the 2017 wheat crop. It can be seen that the majority of the crop had jumped a Protein grade, i.e., APW to H2 and H2 to H1. The farmer calculated that the Yield variation had been reduced by 40% across the field as compared with 2016, and that his Yield was 0.4Tonne/ha more than the local average. Based on the increase in Protein payments and Yield, the farmer reported that he made an additional \$2482 or \$13.61/ha in this field alone through the use of the CropScan On Combine Analyser and the subsequent VRF strategy that the 2016 maps showed him.

Another example is from Leeton Ryan, Woomalang, Victoria, who fitted a CropScan 3000H Grain Analyser to a CaseIH 8240 combine in the 2016. The 3000H records a protein, moisture and oil, along with the longitude and latitude every 8-12 seconds as the combine strips the grain. The yield data was collected from an on board yield monitor. He also collected data for Elevation which showed the undulating terrain on his farm. Figure 9 shows the various maps generated for this one wheat field.

Based on the 2016 maps, Leeton determined three zones in the field whereby he could apply Nitrogen in the form of Urea at rates related to the amount of Nitrogen removed from the field.

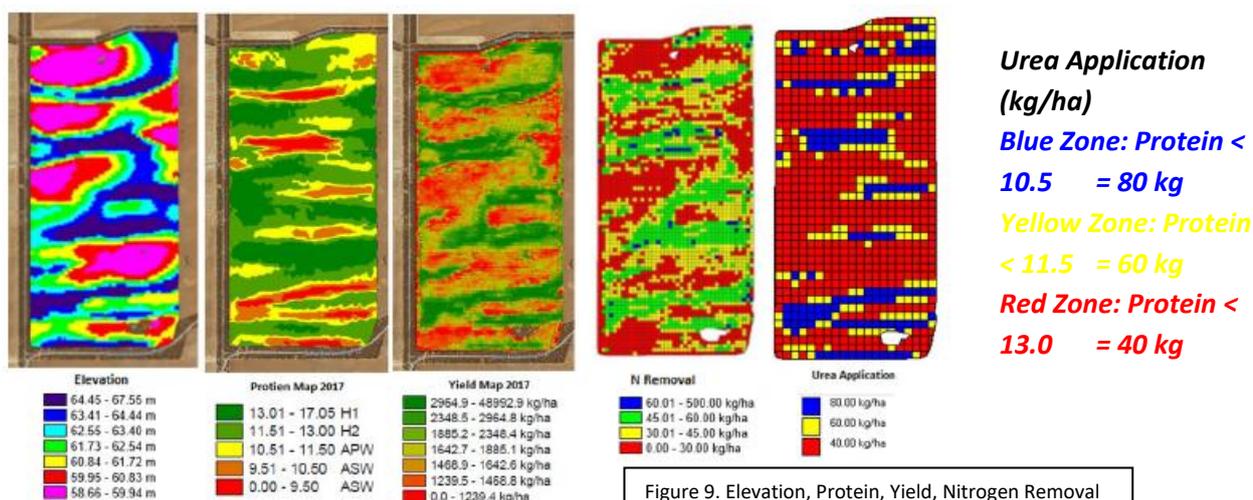

Figure 9. Elevation, Protein, Yield, Nitrogen Removal and Protein/Yield Correlation maps.

Urea Application (kg/ha)
Blue Zone: Protein < 10.5 = 80 kg
Yellow Zone: Protein < 11.5 = 60 kg
Red Zone: Protein < 13.0 = 40 kg

Leeton's objectives are to use this simple VRF strategy to top dress his fields so that he could increase the yield and protein payments.

A third example is from Adam Gurr, Brandon, Manitoba, who installed a CropScan 3000H in 2017 onto his Claas Lexion combine. His soybean maps provide examples of how Protein varies in crops other than cereals. Figure 10 shows maps for Protein, Yield, Protein/Yield Correlation and a VFR prescription for Nitrogen prescription based on these maps.

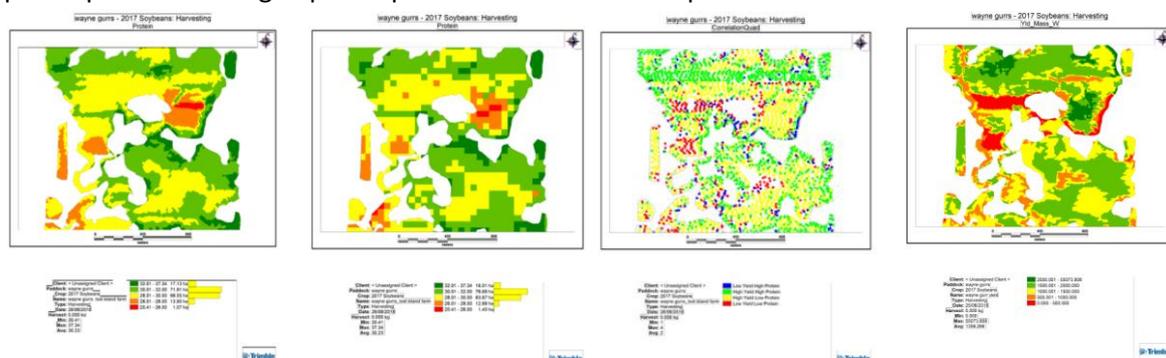

Figure 10. Yield, Protein, Protein/Yield Correlation and VFR Urea Prescription maps

The protein varied across this field from 20% to 37% with an average of 32% for loads delivered to the elevator. It is generally expected that soybeans will exhibit an inverse relation between Yield and Protein, i.e. the Dilution Theory. Figure 10, Yield/Protein Correlation Map, shows areas in the field based on the correlation between protein and yield. The Green and Red areas do not follow the Dilution Theory. The Yellow areas are where the yield was above the average for the field and the protein was less than the average. In the Yellow areas, it is suggested that by increasing the Nitrogen fertilization rate would increase Yield and Protein.

Discussion:

If the drawback for VRF technology lies in the complexity of the maps and the interpretation of the many layers of data, then On the Go Protein analysis using an On Combine NIR Analyser provides a very simple means for farmers and their agronomists to capture 20-30% Yield improvements. The "Low hanging fruit", i.e., the first 20-30% Yield improvements are not the end of the story. Protein plus Yield tells the complete story as to the availability and uptake of nutrients including Nitrogen, Sulphur, Potassium and Phosphorus. The CropScan 3300H On Combine Analyser adds several layers of agronomic data that has been missing from the PA puzzle. Michael Eryes, Field Systems Australia, SA, states:

"The Yield map correlates directly to soil performance and the Protein map is a very good proxy for plant performance. The Nitrogen data is what makes everything else fit together, i.e., productivity and performance. The on combine protein analyser is a tool of exceptional value whose true value is only just starting to be well enough understood"
